

High-Performance Carry Chains for FPGA's

Scott Hauck, *Member, IEEE*, Matthew M. Hosler, and Thomas W. Fry

Abstract—Carry chains are an important consideration for most computations, including FPGA's. Current FPGA's dedicate a portion of their logic to support these demands via a simple ripple carry scheme. In this paper, we demonstrate how more advanced carry constructs can be embedded into FPGA's, providing significantly higher performance carry computations. We redesign the standard ripple carry chain to reduce the number of logic levels in each cell. We also develop entirely new carry structures based on high-performance adders such as carry select, carry lookahead, and Brent-Kung. Overall, these optimizations achieve a speedup in carry performance of 3.8 times over current architectures.

Index Terms—Addition, arithmetic, carry chains, FPGA.

I. INTRODUCTION

ALTHOUGH originally intended as a way to efficiently handle random logic tasks in standard hardware systems, FPGA's have become the driving force behind a new computing paradigm. By mapping algorithms to these FPGA's, significant performance benefits can be achieved. However, in order to achieve these gains, the FPGA resources must be able to efficiently support the computations required in the target application.

The key to achieving high-performance hardware implementations is to optimize the circuit's critical path. For most datapath circuits, this critical path goes through the carry chain used in arithmetic and logic operations. In an arithmetic circuit such as an adder or subtractor, this chain represents the carries from bit position to bit position. For logical operations such as parity or comparison, the chain communicates the cumulative information needed to perform these computations. Optimizing such carry chains is a significant area of VLSI design and is a major focus of high-performance arithmetic circuit design.

Recently, several papers have focused on creating efficient implementations of high-performance adders in FPGA's [3], [10], [11]. These approaches do not seek to modify the underlying architecture of the FPGA, but instead use the existing ripple carry structure of the FPGA's for their implementations. In another work, Woo modified the architecture of the FPGA to change linear cascading chains into tree structured cascade circuits [8]. This modification significantly reduced the delay of cascade circuits. However, the equally important carry chains were not investigated.

In this paper, we will discuss methods of significantly improving the performance of carry computations in FPGA's by

redesigning the FPGA architecture itself. In order to support datapath computations, most FPGA's already include special resources specifically optimized for implementing carry computations. However, because these resources use a relatively simple ripple carry scheme, carry computations can still be a major performance bottleneck. We will show that creating new carry schemes for the FPGA architecture can significantly improve its performance for all datapath operations with a relatively insignificant increase in chip area.

II. BASIC RIPPLE CARRY CELL

A basic ripple carry cell, similar to that found in the Altera 8000 series FPGA's [1], is shown in Fig. 1(a). Mux 1, combined with the two-input lookup tables (2-LUT's) feeding into it, creates a three-input lookup table (3-LUT). This element can produce any Boolean function of its three inputs. Two of its inputs (X and Y) form the primary inputs to the carry chain. The operands to the arithmetic or logic function being computed are sent in on these inputs, with each cell computing one bit position's result. The third input can be either another primary input (Z), or the carry from the neighboring cell, depending on the programming of mux 2's control bit. The potential to have Z replace the carry input is provided so that an initial carry input can be provided to the overall carry chain (useful for incrementers, combined adder/subtractors, and other functions). Alternatively, the logic can be used as a standard 3-LUT for functions that do not need a carry chain. An additional 3-LUT (not shown in the figure) is contained in each cell, which can be used to compute the sum for addition, or other functions.

Before we discuss modifications to this adder cell to improve performance, it is important to understand the role of the "Cout1" and "Cout0" signals in the carry chain. Cout1 and Cout0 are the outputs of the two 2-LUT's calculated such that Cout1 is function of A and B where C_{in} is true and Cout0 is a function of A and B where C_{in} is false. In the case of a normal adder, Cout1 and Cout0 are given by (1) and (2)

$$Cout1 = cout(A, B, 1) = A \text{ AND } B \quad (1)$$

$$Cout0 = cout(A, B, 0) = A \text{ OR } B. \quad (2)$$

During carry computations the C_{in} input that controls mux 1 chooses which of these two signals will be the C_{in} for the next stage in the carry chain. If C_{in} is true, $Cout = Cout1$, while if C_{in} is false, $Cout = Cout0$. Thus, Cout1 is the output whenever $C_{in} = 1$, while Cout0 is the output whenever $C_{in} = 0$. If we consider the possible combinations of values Cout1 and Cout0, we can assume there are four possibilities, three of which correspond to concepts from standard adders (Table I). If both

$Cout0$ and $Cout1$ are true, $Cout$ is true no matter what Cin is, which is the same as the “generate” state in a standard adder. Likewise, when both $Cout0$ and $Cout1$ are false, $Cout$ is false regardless of the state of Cin , and this combination of $Cout1$ and $Cout0$ signals is the “kill” state for this carry chain. If $Cout0$ and $Cout1$ are different, the $Cout$ output will depend on the Cin input. When $Cout0 = 0$ and $Cout1 = 1$, the $Cout$ output will be identical to the Cin input, which is the normal “propagate” state for this carry chain. The last state, with $Cout0 = 1$ and $Cout1 = 0$, is not found in normal adders. In this state, the output still depends on the input, but in this case the $Cout$ output is the inverse of the Cin input. We will call this state “inverse propagate.”

For a normal adder, the inverse propagate state is never encountered. Thus, it might be tempting to disallow this state. However, for other computations this state is essential. For example, consider implementing a parity circuit with this carry chain, where each cell takes the XOR of the two inputs, X and Y , and the parity of the neighboring cell. If X and Y are both zero, the $Cout$ of the cell will be identical to the parity of the neighboring cell, which is brought in on the Cin signal. Thus, the cell is in normal propagate mode. However, if X is true and Y is false, then the $Cout$ will be the opposite of Cin , since $(1 \oplus 0 \oplus Cin) = \overline{Cin}$. Thus, the inverse propagate state is important for implementing circuits like parity, and thus supporting this state in the carry chain we increase the types of circuits that can be efficiently implemented. In fact, by allowing an inverse propagate mode in the carry chain, the chain can be viewed as simply a series of 3-LUT's connected together, allowing any critical path to be implemented efficiently.

One last issue must be considered in this carry chain structure. In an FPGA, the cells represent resources that can be used to compute arbitrary functions. However, the location of functions within this structure is completely up to the user. Thus, a user may decide to start or end a carry computation at any place in the array. In order to start a carry chain, we must program the first cell in the carry chain to ignore the Cin signal. One easy way to

do this is to program mux 2 in the cell to route input Z to mux 1 instead of Cin . For situations where one wishes to have a carry input to the first stage of an adder (which is useful for implementing combined adder/subtractors as well as other circuits), this is the right solution. However, in other cases this may not be possible. The first stage in many carry computations is only a two-input function, and forcing the carry chain to wait for the arrival of an additional, unnecessary input will only needlessly slow down the circuit's computation. This is not necessary. In these circuits, the first stage is only a two-input function. Thus, either 2-LUT in the cell could compute this value. If we program both 2-LUT's with the same function, the output will be forced to the proper value regardless of the input, and thus either the Cin or the Z signal can be routed to mux 1 without changing the computation. However, this is only true if mux 1 is implemented such that if the two inputs to the mux are the same, the output of the mux is identical to the inputs regardless of the state of the select line. Fig. 1(b) shows an implementation of a mux that does not obey this requirement. Since the carry chain is part of an FPGA, the input to this mux could be connected to some unused logic in another row which is generating unknown values. If that unused logic had multiple transitions which caused the signal to change quicker than the gate could react, then it is possible that the select signal to this mux could be stuck midway between true and false (2.5 V for 5-V CMOS). In this case, it will not be able to pass a true value from the input to the output, and thus will not function properly for this application. However, a mux built like that in Fig. 1(c), with both n-transistor and p-transistor pass gates, will operate properly for this case. Thus, we will assume throughout this paper that all muxes in the carry chain are built with the circuit shown in Fig. 1(c), though any other mux implementation with the same property could be used (including tristate driver based muxes which can restore signal drive and cut series R-C chains).

III. DELAY MODEL

To initially quantify the performance of the carry chains developed in this paper, a unit gate delay model will be used: all simple gates of two or three inputs that are directly implementable in one logic level in CMOS are considered to have a delay of one. All other gates must be implemented in such gates and have the delay of the underlying circuit. Thus, inverters and two-three-input NAND and NOR gates have a delay of one. A 2:1 mux has a delay of one from the $I0$ or $I1$ inputs to the output, but has a delay of two from the select input to the output due to the inverter delay [see Fig. 1(c)]. The delay of the 2-LUT's, and any routing leading to them, is ignored since this will be a constant delay for all the carry chains developed in this paper. This delay model will be used to initially discuss different carry chain alternatives and their advantages and disadvantages. Precise circuit timings are also generated using Spice on the VLSI layouts of the carry chains, as discussed later in this paper.

IV. OPTIMIZED RIPPLE CARRY CELL

As we discussed in an earlier section, the ripple carry design of Fig. 1(a) is capable of implementing most interesting carry

computations. However, it turns out that this structure is significantly slower than it needs to be since there are two muxes on the carry chain in each cell (mux 1 and 2). Specifically, the delay of this circuit is one for the first cell plus three for each additional cell in the carry chain (one delay for mux 2 and two delays for mux 1), yielding an overall delay of $3n - 2$ for an n -cell carry chain. Note that we assume the longest path through the carry chain comes from the 2-LUT's and not input Z since the delay through the 2-LUT's will be larger than the delay through mux 2 in the first cell.

We can reduce the delay of the ripple carry chain by removing mux 2 from the carry path. As shown in Fig. 2(a), instead of choosing between C_{in} and Z for the select line to the output mux, we instead have two separate muxes, 1 and 2, controlled by C_{in} and Z , respectively. Then, the circuit chooses between these outputs with mux 3. In this design, there is a delay of one in the first cell of a carry chain, a delay of three in the last cell (two for mux 1 and one for mux 3), and a delay of only two for all intermediate cells. Thus, the delay of this design is only $2n$ for an n -b ripple carry chain, yielding up to a 50% faster circuit than the original design.

Unfortunately, the circuit in Fig. 2(a) is not logically equivalent to the original design. The problem is that the design can no longer use the Z input in the first cell of a carry chain as an initial carry input, since Z is only attached to mux 2, and mux 2 does not lead to the carry path. The solution to this problem is the circuit shown in Fig. 2(b). For cells in the middle of a carry chain, mux 2 is configured to pass C_{out1} , and mux 3 passes C_{out0} . Thus, mux 4 receives C_{out1} and C_{out0} and provides a standard ripple carry path. However, when we start a carry chain with a carry input (provided by input Z), we configure mux 2 and mux 3 to both pass the value from mux 1. Since this means that the two main inputs to mux 4 are identical, the output of mux 4 (C_{out}) will automatically be the same as the output of mux 1, ignoring C_{in} . Mux 1's main inputs are driven by two 2-LUT's controlled by X and Y , and thus mux 1 forms a 3-LUT with the other 2-LUT's. When mux 2 and mux 3 pass the value from mux 1, the circuit is configured as a 3-LUT starting a carry chain, while when mux 2 and mux 3 choose their other input (C_{out0} and C_{out1} , respectively) the circuit is configured to continue the carry chain. This design is therefore functionally equivalent to the design in Fig. 1(a). However, carry chains built from this design have a delay of three in the first cell (one in mux 1, one in mux 2 or mux 3, and one in mux 4) and two in all other cells in the carry chain, yielding an overall delay of $2n + 1$ for an n -b carry chain. Thus, although this design is one gate delay slower than that of Fig. 2(a), it provides the ability to have a carry input to the first cell in a carry chain, something that is important in many computations. Also, for carry computations that do not need this feature, the first cell in a carry chain built from Fig. 2(b) can be configured to bypass mux 1, reducing the overall delay to $2n$, which is identical to that of Fig. 2(a). On the other hand, in order to implement an n -b carry chain with a carry input, the design of Fig. 2(a) requires an additional cell at the beginning of the chain to bring in this input, resulting in a delay of $2(n + 1) = 2n + 2$, which is slower than that of the design in Fig. 2(b). Thus, the design of Fig. 2(b) is the preferred ripple carry design among those presented so far.

VALUES AND THE RESULTING CARRY OUTPUT. THE FINAL COLUMN
LISTS THE NAME FOR THAT COMBINATION

C_{out0}	C_{out1}	C_{out}	Name
0	0	0	Kill
0	1	C_{in}	Propagate
1	0	$\overline{C_{in}}$	Inverse Propagate
1	1	1	Generate

V. HIGH-PERFORMANCE CARRY LOGIC FOR FPGA'S

In the previous section, we discussed how to optimize a ripple carry chain structure for use in FPGA's. While this provides some performance gain over the basic ripple carry scheme found in many current FPGA's, it is still much slower than what is done in custom logic. There have been tremendous amounts of work done on developing alternative carry chain schemes that overcome the linear delay growth of ripple-carry adders. Although these techniques have not yet been applied to FPGA's, in this paper we will demonstrate how these advanced adder techniques can be integrated into reconfigurable logic. The basis for all of the high-performance carry chains developed in this paper will be the carry cell of Fig. 2(c). This cell is very similar to that of Fig. 2(b), except that the actual carry chain (mux 4) has been abstracted into a generic "fast carry logic" unit and mux 5 has been added. This extra mux is present because although some of our faster carry chains will have much quicker carry propagation for long carry chains, they do add significant delay to non-carry computations. Thus, when the cell is used as just a normal

3-LUT, using inputs X , Y , and Z , mux 5 allows us to bypass the carry chain by selecting the output of mux 1.

The important thing to realize about the logic of Fig. 2(c) is that any logic that can compute the value

$$Cout_i = (Cout_{i-1} * C1_i) + (\overline{Cout_{i-1}} * C0_i) \quad (3)$$

where i is the position of the cell within the carry chain and can provide the functionality necessary to support the needs of FPGA computations. Thus, the fast carry logic unit can contain any logic structure implementing this computation. In this paper, we will look at four different types of carry logic: carry select, carry lookahead (including Brent-Kung), variable bit, and ripple carry (discussed previously). Note that because of the needs and requirements of carry chains for FPGA's, we will have to develop new circuits, inspired by the standard adder structures, but which are more appropriate for FPGA's. The main difference is that we no longer have just the generate, propagate, and kill states for an adder—we must also support inverse propagate. These four states are encoded on signals $C1$ and $C0$ as shown in Table I. Also, while standard adders are concerned only with the maximum delay through an entire N -b adder structure, the delay concerns for FPGA's are more complicated. Specifically, when an N -b carry chain is built into the architecture of an FPGA, it does not represent an actual computation, but only the potential for a computation. A carry chain resource may span the entire height of a column in the FPGA, but a mapping to the logic may use only a small portion of this chain, with the carry logic in the mapping starting and ending at arbitrary points in the column. Thus, we are concerned with not just the carry delay from the first to the last position in a carry chain, but must consider the delay for a carry computation beginning and ending at any point within this column. For example, even though the FPGA architecture may provide support for carry chains of up to 32 b, it must also efficiently support 8-b carry computations placed at any point within this carry chain resource.

VI. CARRY SELECT

The problem with a ripple carry structure is that the computation of the $Cout$ for bit position i cannot begin until after the computation has been completed in bit positions $0 \dots i - 1$. A carry select structure overcomes this limitation. The main observation is that for any bit position, the only information it receives from the previous bit positions is its Cin signal, which can be either true or false. In a carry select adder, the carry chain is broken at a specific column, and two separate additions occur: one assuming the Cin signal is true, the other assuming it is false. These computations can take place before the previous columns complete their operation, since they do not depend on the actual value of the Cin signal. This Cin signal is instead used to determine which adder's outputs should be used. If the Cin signal is true, the output of the following stages comes from the adder that assumed that the Cin would be true. Likewise, a false Cin chooses the other adder's output. This splitting of the carry chain can be done multiple times, breaking the computation into several pairs of short adders with output muxes choosing which adder's output to select. The length of the adders and

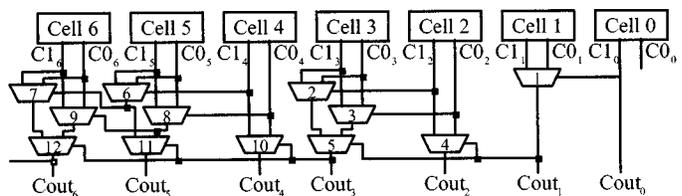

Fig. 3. Carry select structure.

the breakpoints are carefully chosen such that the small adders finish computation just as their Cin signals become available. Short adders handle the low-order bits, and the adder length is increased further along the carry chain, since later computations have more time until their Cin signal is available.

A carry select carry chain structure for use in FPGA's is shown in Fig. 3. The carry computation for the first two cells is performed with the simple ripple-carry structure implemented by mux 1. For cells 2 and 3, we use two ripple carry adders, with one adder (implemented by mux 2) assuming the Cin is true and the other (mux 3) assuming the Cin is false. Then, muxes 4 and 5 pick between these two adders' outputs based on the actual Cin coming from mux 1. Similarly, cells 4–6 have two ripple carry adders (mux 6 and 7 for a Cin of one, mux 8 and 9 for a Cin of zero), with output muxes (muxes 10–12) deciding between the two based upon the actual Cin (from mux 5). Subsequent stages will continue to grow in length by one, with cells 7–10 in one block, cells 11–15 in another, and so on. Timing values showing the delay of the carry select carry chain relative to other carry chains will be presented later in this paper.

VII. VARIABLE BLOCK

Like the carry select carry chain, a variable block structure [5] consists of blocks of ripple carry elements (Fig. 4). However, instead of precomputing the $Cout$ value for each possible Cin value, it instead provides a way for the carry signal to skip over intermediate cells where appropriate. Contiguous blocks of the computation are grouped together to form a unit with a standard ripple carry chain. As part of this block, logic is included to determine if all of the cells are in their propagate state. If so, the $Cout$ for this block is immediately set to the value of the block's Cin , allowing the carry chain to bypass this block's normal carry chain on its way to later blocks. The Cin still ripples through the block itself, since the intermediate carry values must also be computed. If any of the cells in the carry chain are not in propagate mode, the $Cout$ output is generated normally by the ripple carry chain. While this carry chain does start at the block's Cin signal and leads to the block's $Cout$, this long path is a false path. That is, since there is some cell in the block that is not in propagate mode, it must be in generate or kill mode, and, thus, the block's $Cout$ output does not depend on the block's Cin input.

A major difficulty in developing a version of the variable block carry chain for inclusion in an FPGA's architecture is the need to support both the propagate and inverse propagate states of the cells. To do this, we compute two values. First, we check to see if all the cells are in some form of propagate mode (either

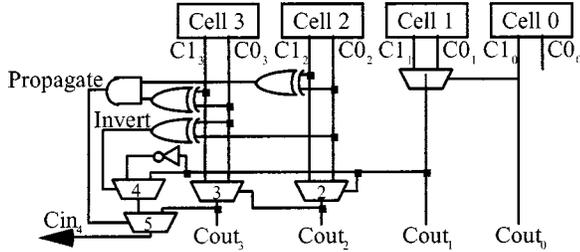

Fig. 4. The variable block carry structure. Mux 1 performs an initial two-stage ripple carry. Muxes 2–5 form a 2-b variable block. Mux 5 decides whether the C_{in} signal should be sent directly to C_{out} , while mux 4 decides whether to invert the C_{in} signal or not.

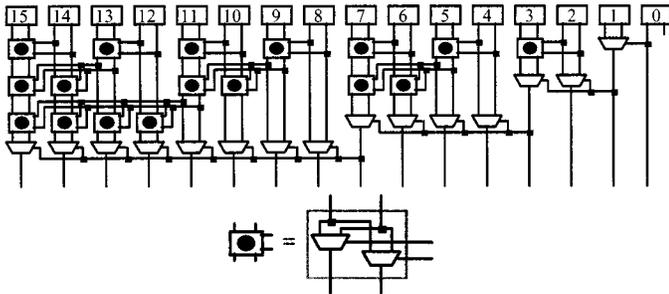

Fig. 5. The three-level 16-b Brent-Kung structure. At right are the details of the concatenation block. Note that once the C_{in} has been computed for a given stage, a mux is used in place of a concatenation block.

normal propagate or inverse propagate) by ANDing together the XOR of each stage's $C1$ and $C0$ signals. If so, we know that the C_{out} function will be equal to either C_{in} or $\overline{C_{in}}$. To decide whether to invert the signal or not, we must determine how many cells are in inverse propagate mode. If the number is even (including zero) the output is not inverted, while if the number is odd the output is inverted. The inversion check can be done by looking for inverse propagate mode in each cell and XORing the results. To check for inverse propagate, we only look at the $C0$ signal from each cell. If this signal is true, the cell is in either generate or inverse propagate mode, and if it is in generate mode the inversion signal will be ignored anyway (we only consider inverting the C_{in} signal if all cells are in some form of propagate mode). Note that for both of these tests we can use a tree of gates to compute the result. Also, since we ignore the inversion signal when we are not bypassing the carry chain, we can use $C1$ as the inverse of $C0$ for the inversion signal's computation, which avoids the added inverter in the XOR gate.

The organization of the blocks in the variable block carry structure bears some similarity to the carry select structure. The early stages of the structure grow in length, with short blocks for the low-order bits, building in length further in the chain in order to equalize the arrival time of the carry from the block with that of the previous block. However, unlike the c carry select structure, the variable block adder must also worry about the delay from the C_{in} input through the block's ripple chain. Thus, after the carry chain passes the midpoint of the logic, the blocks begin decreasing in length. This balances the path delays in the system and improves performance. The division of the overall

structure into blocks depends on the details of the logic structure and the length of the entire computation. We use a block length (from low-order to high-order cells) of 2, 2, 4, 5, 7, 5, 4, 2, and 1 for a normal 32-b structure. The first and last block in each adder is a simple ripple carry chain, while all other blocks use the variable block structure. Delay values of the variable block carry chain relative to other carry chains will be presented later in this paper.

VIII. CARRY LOOKAHEAD AND BRENT-KUNG

There are two inputs to the fast carry logic in Fig. 2(c): $C1_i$ and $C0_i$. The value of $C1_i$ is programmed by the LUT's so that it contains the value that C_{out_i} should have if C_{in_i} is true. Similarly, the value of $C0_i$ is programmed by the LUT's so that it contains the value that C_{out_i} should have if C_{in_i} is false. We can combine the information from two stages together to determine what the C_{out} of one stage will be given the C_{in} of the previous stage. For example

$$C1_{i,i-1} = (C1_{i-1} * C1_i) + (\overline{C1_{i-1}} * C0_i) \quad (4)$$

$$C0_{i,i-1} = (C0_{i-1} * C1_i) + (\overline{C0_{i-1}} * C0_i) \quad (5)$$

where $C1_{x,y}$ is the value of C_{out_x} assuming that $C_{in_y} = 1$. This allows us to halve the length of the carry chain, since once these new values are computed a single mux can compute C_{out_i} given $C_{in_{i-1}}$. In fact, similar rules can be used recursively, halving the length of the carry chain with each application. Specifically

$$C1_{i,k} = (C1_{j-1,k} * C1_{i,j}) + (\overline{C1_{j-1,k}} * C0_{i,j}) \quad (6)$$

$$C0_{i,k} = (C0_{j-1,k} * C1_{i,j}) + (\overline{C0_{j-1,k}} * C0_{i,j}) \quad (7)$$

assuming $i > j > k$. The digital logic computing both of these functions will be called a concatenation box. The Brent-Kung carry chain [2] consists of a hierarchy of these concatenation boxes, where each level in the hierarchy halves the length of the carry chain, until we have computed $C1_{i,0}$ and $C0_{i,0}$ for each cell i . A single level of muxes at the bottom of the Brent-Kung carry chain can then use these values to compute the C_{out} for each cell given a C_{in} . The Brent-Kung carry chain is shown in Fig. 5.

The Brent-Kung adder is a specific case of the more general carry lookahead adder [6]. In a carry lookahead adder, a single level of concatenation combines together the carry information from multiple sources. A typical carry lookahead adder will combine four cells together in one level (computing $C1_{i,i-3}$ and $C0_{i,i-3}$), combine four of these new values together in the next level, and so on.

However, while a combining factor of four is considered optimal for a standard adder, in FPGA's combining more than two values in a level is not advantageous. The problem is that although the logic to concatenate N values together grows linearly for a normal adder, it grows exponentially for a reconfigurable carry chain. For example, to concatenate three values together for a normal adder we have

$$C_{x,z} = G_x + (P_x * C_{x-1,z}) \quad (8)$$

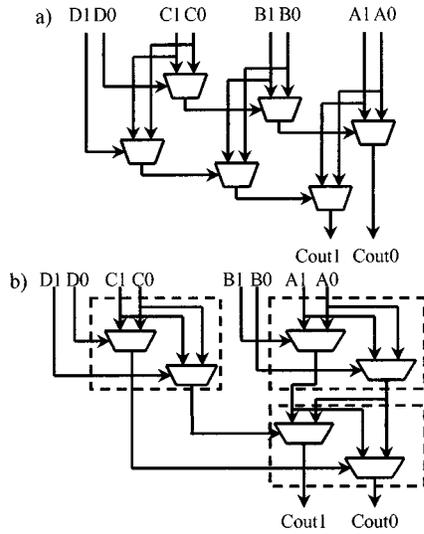

Fig. 6. Concatenation boxes. (a) A four-cell concatenation box and (b) its equivalent made up of only two-cell concatenation boxes.

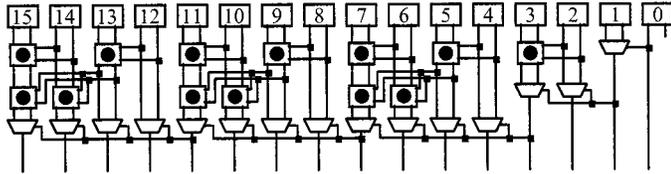

Fig. 7. A two-level 16-b carry lookahead structure.

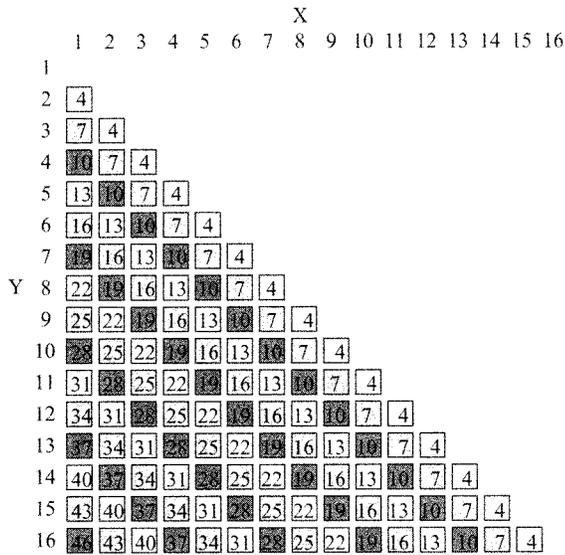

Fig. 8. The delays of a basic ripple carry chain which start at cell X and end at cell Y using the theoretical delay model.

where P_x and G_x are the propagate and generate values of the current cell. However, to concatenate three values together for a reconfigurable carry chain together, we have

$$C1_{w,z} = (C1_{x-1,z} * C1_{w,x}) + (\overline{C1_{x-1,z}} * C0_{w,x}) \quad (9)$$

$$\begin{aligned} &= ((C1_{y-1,z} * C1_{x-1,y}) + (\overline{C1_{y-1,z}} * C0_{x-1,y})) \\ &\quad * C1_{w,x} + ((C1_{y-1,z} * \overline{C1_{x-1,y}}) \\ &\quad + (\overline{C1_{y-1,z}} * C0_{x-1,y})) * C0_{w,x}. \end{aligned} \quad (10)$$

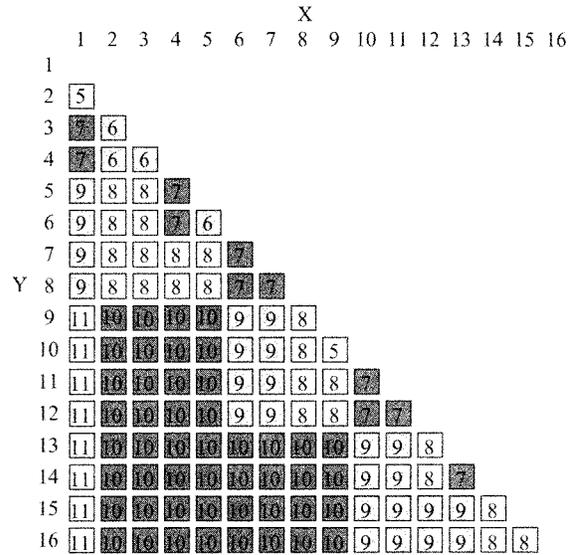

Fig. 9. The delays of a Brent-Kung carry chain which start cell X and end at cell Y using the theoretical delay model.

An alternative way to see why combining four cells together in one level is bad for FPGA's is to consider how this combining would be implemented. Fig. 6(a) shows a concatenation box that takes its input from four different cells. Fig. 6(b) then shows how a four-cell concatenation box can be built using only three two-cell concatenation boxes. This second method of creating a four-cell concatenation box is really the equivalent of a two-level carry lookahead adder using two-cell concatenation boxes. Using the simple delay model discussed earlier, the delay for the four-cell concatenation box in Fig. 6(a) is six units since the signal must travel through three muxes. The delay for the four-cell concatenation box equivalent found in Fig. 6(b), however, is only four units since the signal must travel through only two muxes. Thus, a four-cell concatenation box is never used since it can always be implemented with a smaller delay using two-cell concatenation boxes. Therefore, the Brent-Kung structure is the best approach.

Another option in carry lookahead adders is the possibility of using fewer levels of concatenation than a Brent-Kung structure. Specifically, a Brent-Kung structure for a 32-b adder would require four levels of concatenation. While this allows Cin_0 to quickly reach $Cout_{31}$, there is a significant amount of delay in the logic that computes the individual $C1_{i,0}$ and $C0_{i,0}$ values. We can instead use fewer levels than the complete hierarchy of the Brent-Kung adder and simply ripple together the top-level carry computations of smaller carry lookahead adders. Specifically, if we talk about an N -level carry lookahead adder, that means that we only apply N levels of two-input concatenation units. A two-level 16-b carry lookahead carry chain is shown in Fig. 7.

IX. CARRY CHAIN PERFORMANCE

In order to compare the carry chains developed in this paper, we computed the performance of the carry chains of different lengths. The delay is computed from the output of the 2-LUT's in one cell to the final output (F) in another using the simple

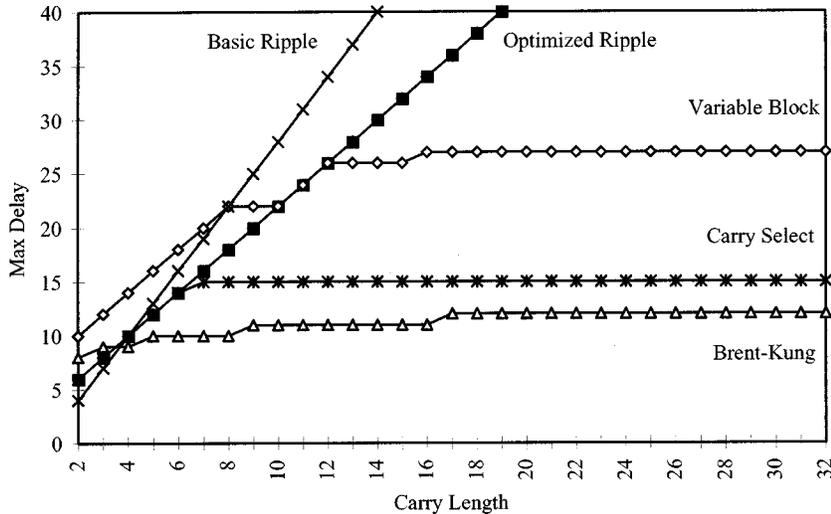

Fig. 10. A comparison of the various carry chain structures. The delays represent the maximum delay for an N -b adder placed anywhere within a 32-b carry structure.

delay model discussed earlier in the delay model section. This simple model calculates a delay based on the number of gates that must be traversed by a signal. Precise circuit timings are discussed later in this paper. Figs. 8 and 9 show the delays of a carry chain starting at cell X and ending at cell Y for the basic ripple and Brent-Kung carry chains, respectively. These figures show how the delay patterns are different for each carry chain. One important issue to consider is what delay we should use to compare carry chain performance. While the carry chain structure is dependent on the length of the carry computation supported by the FPGA (such as the variable block segmentation), the user may decide to use any contiguous subsequence of the carry chain's length for their mapping. To deal with this, we assume that the FPGA's are built to support up to a 32-b carry chain and record the maximum carry chain delay for any length L carry computation within this structure. That is, since we do not know where the user will begin their carry computation within the FPGA architecture, we measure the worst case delay for a length L carry computation starting at any point in the FPGA. Note that this delay is the critical path within the L -b computation, which means carries starting and ending anywhere within this computation are considered.

Fig. 10 shows the maximum carry delays for each of the carry structures discussed in this paper, as well as the basic ripple carry chain found in current FPGA's. These delays are based on the simple delay model that was discussed earlier. More precise delay timings from VLSI layouts of the carry chains will be discussed later. As can be seen, the best carry chain structure for short distances is different from the best chain for longer computations, with the basic ripple carry structure providing the best delay for length 2 carry computations, while the Brent-Kung structure provides the best delay for computations of four bits or more. In fact, the ripple carry structure is more than twice as fast as the Brent-Kung structure for 2-b carry computations, yet is approximately eight times slower for 32-b computations. However, short carries are often not that critical, since they can be supported by the FPGA's normal routing structure and will tend not to dominate the performance of the overall system. There-

TABLE II
A COMPARISON OF THE DELAYS OF DIFFERENT STRUCTURES FOR (a) A 32-B CARRY AND (b) A NONCARRY COMPUTATION OF A FUNCTION, $f(X, Y, Z)$

Carry Chain	32-bit delay (ns)	3-LUT delay (ns)
Basic Ripple Carry	23.4	1.6
Optimized Ripple	18.7	2.5
Brent-Kung	6.1	2.1

fore, we believe that the Brent-Kung structure is the preferred structure for FPGA carry computations and that it is capable of providing significant performance improvement over current FPGA carry chains.

In this paper, we also considered other carry lookahead adder designs which do not use as many levels of concatenation boxes as a full Brent-Kung adder. However, as can be seen in Fig. 11, the other carry structures provide only modest improvements over the Brent-Kung structure for short distances and perform significantly worse than the Brent-Kung structure for longer carry chains.

Another consideration when choosing a carry chain structure is the size of the circuit. Fig. 12 shows the number of transistors that are used in the design of the basic ripple, optimized ripple, carry select, variable block, and Brent-Kung carry chains. The transistor counts here are based on a CMOS implementation of the inverting tristate mux. One concern with the Brent-Kung structure is that it requires four times more transistors to implement than the basic ripple carry. However, in typical FPGA's the carry structure occupies only a tiny fraction of the chip area, since the programming bits, LUT's, and programmable routing structures dominate the chip area. Therefore, the increase in chip area required by the higher performance carry chains developed in this paper is relatively insignificant, yet the performance improvements can greatly accelerate many types of applications. The area and performance of the high-performance carry chains with respect to those of the basic ripple carry chains will be discussed further in the next section of this paper.

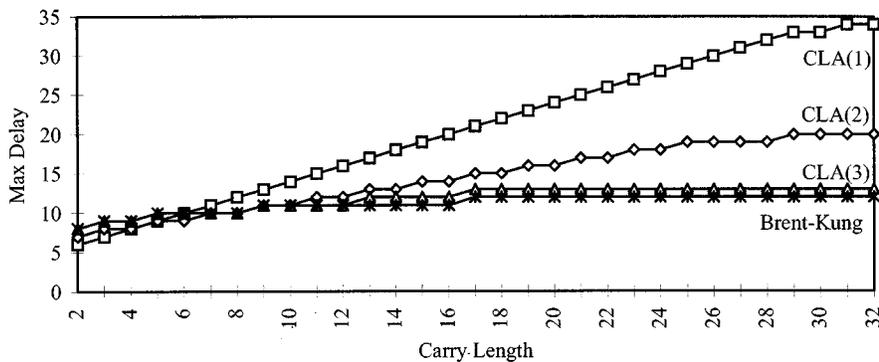

Fig. 11. A comparison of carry lookahead structures. CLA(*i*) represents a Brent-Kung style carry lookahead structure with only *i* levels of concatenation boxes.

X. LAYOUT RESULTS

The results of the simple delay model described earlier suggest that the Brent-Kung carry chain has the best performance of any of the carry chains. However, the performance results used to make this decision are based only on the simple delay

model, which may not accurately reflect the true delays. The simple delay model does not take into account transistor sizes or routing delays. Therefore, in order to get more accurate comparisons, the carry chains were sized using logical effort [7], layouts were created, and timing numbers were obtained from Spice for a 0.6- μ m process. Only the most promising carry chains were chosen for implementation. These include the basic ripple carry, which can be found in current FPGA's, as well as the new optimized ripple and Brent-Kung carry chains.

Table II shows the delays of a 32-b carry for the carry chains that were implemented. Notice that the delay for basic ripple carry chain is 23.4 ns, and the delay for the optimized ripple carry chain is 18.7 ns resulting in a speedup of 1.25 times over the basic ripple carry chain. Furthermore, the delay for the Brent-Kung carry chain is only 6.1 ns. Thus, the best carry chain developed here has a delay 3.8 times faster than the basic ripple carry chain used in industry. Table II also shows the delays of the FPGA cell assuming that the cell is programmed to compute a function of three variables and avoid the carry chain [as shown by Mux 5 in Fig. 2(c)]. The delay for the basic ripple carry chain in this case is 1.6 ns, while the delay for

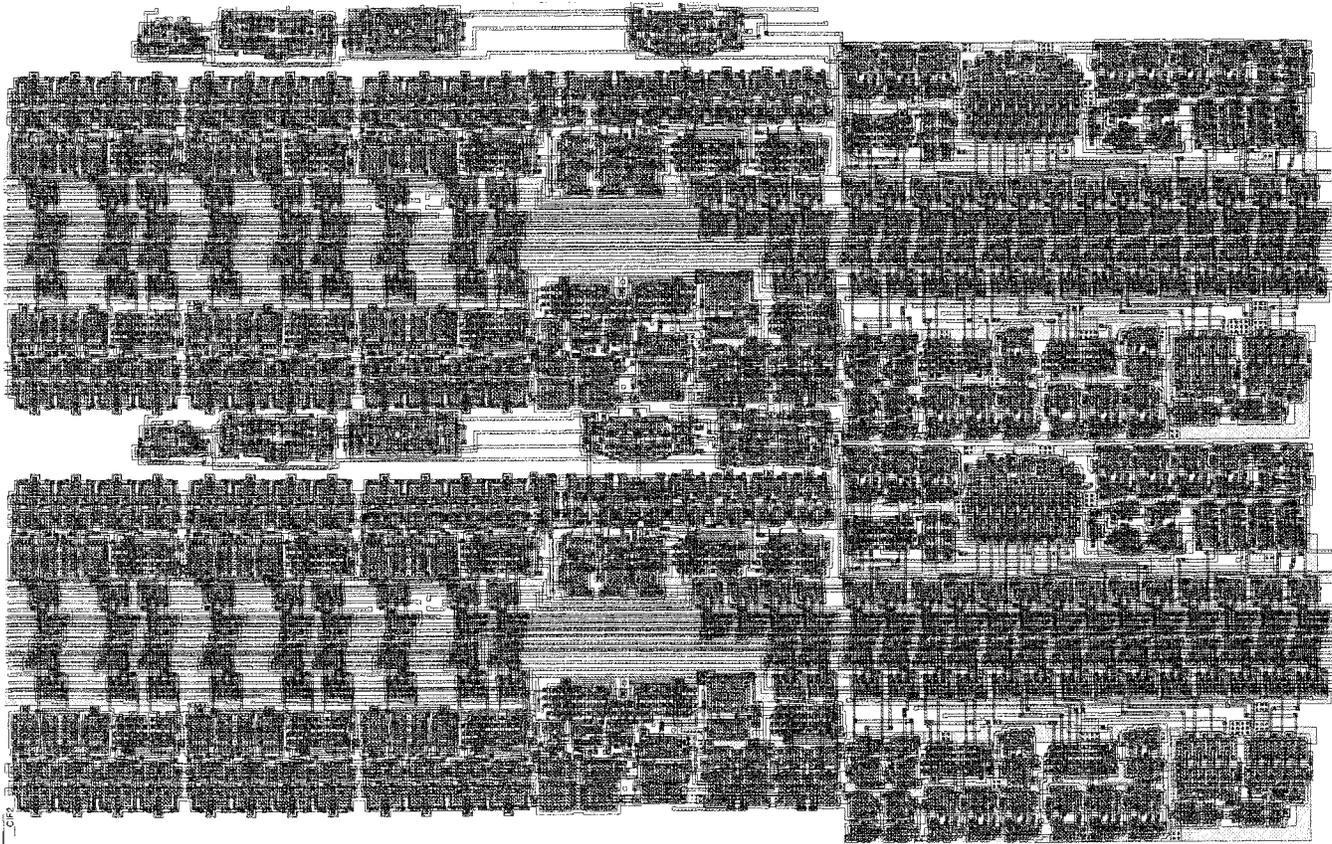

Fig. 14. Two cells from the Chimaera FPGA, including the most complex bit slice of the Brent-Kung adder. The adder logic is the isolated logic in the upper right of each cell (four blocks in the right cell, five in the left). Metal 3 routing (not shown) for other purposes occupies the empty space in the adder. The logic for the entire adder represents approximately 8% of the chip area.

the Brent-Kung carry chain is 2.1 ns. Thus, the Brent-Kung implementation does slow down noncarry operations, but only by a small amount. Table III shows the area of these carry chains as measured from the layouts. One item to note is the size of the Brent-Kung carry chain. Its size is shown as 9.47 times larger than the basic ripple carry chain. This number should be viewed purely as an upper bound, since the layout of the basic ripple carry was optimized much more than the Brent-Kung layout. We believe that further optimization of the Brent-Kung design could reduce its area by $600\,000^2\lambda$, yielding only a factor of a five-size increase over the basic ripple carry scheme.

A more accurate comparison of the size implications of the improved carry chains is to consider the area impact of including these carry chains in an actual FPGA. We have conducted such experiments with the Chimaera FPGA [4], a special-purpose FPGA which has been carefully optimized to reduce the amount of chip area devoted to routing. As shown in Table III, replacing the basic ripple carry structure in the Chimaera FPGA with the Brent-Kung structure results in an area increase of 8.5%. Our estimates of the area increase on a general-purpose FPGA, such as the Xilinx 4000 [9] or Altera 8000 FPGA's, where the more complex routing structure consumes a much greater portion of the chip area, are that the Brent-Kung structure would only increase the total chip area by 1.2%. This is based upon increasing

the portion of Chimaera's chip area devoted to routing up to the 90% of chip area typical in general-purpose FPGA's.

XI. USING THE CARRY CHAIN

Thus far, we have explained why high-performance carry chains should be used in FPGA's. Now we will explain where the carry chain is located in the FPGA and how it is programmed. In our design, the carry chain is row-based and unidirectional as shown in Fig. 13. There is exactly one carry chain per row, and it spans the entire length of that row. The carry chains in different rows are not interconnected. However, normal FPGA routing could connect these carry chains if a larger carry chain is needed.

The Brent-Kung carry chain that we designed is an n -b carry chain where n is a power of two. The carry chain is placed in one row of the FPGA, and it interfaces with the FPGA cells in that row. Each FPGA cell connects to a different part of the carry chain. Since the Brent-Kung carry chain is not uniform, the carry chain logic seen by each FPGA cell will be different. Fig. 14 shows two cells of the Chimaera FPGA and the portion of the Brent-Kung carry chain contained within them.

One additional feature of the carry chain is that it can be broken into smaller, independent carry chains at any point by programming the LUT's. Recall that one LUT produces C_{out1} ,

which is the value of C_{out} if C_{in} is equal to one. Similarly, the other LUT produces C_{out0} , which is the value of C_{out} if C_{in} is equal to zero. In order to break the carry chain, we program the LUT's so that both C_{out1} and C_{out0} have the same value. In this case, C_{out} has the same value regardless of the value of C_{in} , and the original carry chain has been segmented into smaller, independent carry chains.

XII. CONCLUSIONS

One of the critical performance bottlenecks in most systems is the carry chains contained in many arithmetic and logical operations. Current FPGA's optimize for these elements by providing some support specifically for carry computations. However, these systems rely on relatively simple ripple carry structures which provide much slower performance than current high-performance carry chain designs. With the advent of reconfigurable computing and the demands of implementing complex algorithms in FPGA's, the slowdown of carry computations in FPGA's is an even more crucial concern.

In order to speed up the carry structure found in current FPGA's, we developed several innovative techniques. A novel cell design is used to reduce the delay through the cell to a single mux by moving the decision of whether to use the carry chain off of the critical path. This results in approximately a factor of 1.25 speedup over current FPGA carry delays.

High-performance adders are not limited to simple ripple carry schemes and, in fact, rely on more advanced formulations to speed up their computation. However, as we demonstrated in this paper, the demands of FPGA-based carry chains are different than standard adders, especially because of the "inverse propagate" cell state. Thus, we cannot directly take standard high-performance adder carry chains and embed them into current FPGA architectures.

In this paper, we developed novel high-performance carry chain structures appropriate to reconfigurable systems. These include implementations of carry select, variable block, and carry lookahead (including Brent-Kung) adders. We have been able to produce a carry chain that is up to a factor of 3.8 faster than current FPGA structures while maintaining all the flexibility of current systems. This provides a significant performance boost for the implementation of future FPGA-based systems.
